May 13, 2022

Introduction

- ullet Main project goal o overview of two major timing attacks:
 - Kocher's timing attack (1996) [1];
 - Brumley and Boneh's timing attack (2005) [2].
- A timing attack is a type of side-channel attack.
- A side-channel attack exploits physical parameters, such as:
 - execution time;
 - electromagnetic emission;
 - supply current.

Square-and-multiply modular exponentiation

$\textbf{Algorithm 1} \ \, \textbf{Square-and-multiply modular exponentiation algorithm}.$

```
1: function mod\_exp(y, x, n) 
ightharpoonup Computes <math>y^x \mod n

2: R \leftarrow 1

3: for k \leftarrow 0, w - 1 do

4: R \leftarrow (R \cdot R) \mod n

5: if (the k-th bit of x) is 1 then

6: R \leftarrow (R \cdot y) \mod n

7: return R
```

mod_exp is a core operation in public-key cryptosystems, such as:

- RSA:
- Diffie-Hellman key exchange.

Kocher's timing attack - assumptions

Assume an RSA cryptosystem, with $D_k[x] = y^x \mod n$. Now, suppose that an attacker:

- wants to retrieve the private exponent x;
- already knows the first b exponent bits of x;
- can perform as many decryption operations as he wants;
- is able to measure $T := e + \sum_{i=0}^{k-1} t_i$, where:
 - $t_i \rightarrow i$ -th iteration required time for mod_exp(y, x, n);
 - y → any ciphertext;
 - $e \rightarrow$ overhead time.

Kocher's timing attack - pseudocode

Algorithm 2 Kocher's timing attack

- 1: generate s ciphertexts $\{y_1, \ldots, y_s\}$;
- 2: guess the *b*-th exponent bit $d'_b := 0$;
- 3: measure $T_i' = e + \sum_{i=0}^{b-1} t_i', \quad \forall j \in \{1, \dots, s\};$
- 4: estimate Var(T T');
- 5: repeat from step 3. and step 4. with $d'_b := 1$;
- 6: choose $d_h^* \in \{0,1\}$ that minimizes Var(T-T');
- 7: set $d_b \leftarrow d_b^*$;
- 8: set $b \leftarrow b + 1$;
- 9: repeat from step 2. until b > k 1.

In step 3., T' is measured by running mod_exp (y, x_b, n) , where:

•
$$x_b := (d_0 d_1 \cdots d_{b-1} d'_b)_2$$
.

Brumley and Boneh's timing attack - assumptions

Assume an RSA cryptosystem implemented with OpenSSL (0.9.7). Let n = pq be the public modulus, with q < p. Now, suppose that an attacker:

- wants to retrieve the private factor q;
- knows i-1 bits of $q: \{q_0, q_1, \dots, q_{i-1}\};$
- starts to guess q with g:

$$\rightarrow g_0 := q_0, g_1 := q_1, \ldots, g_{i-1} := q_{i-1};$$

 $\rightarrow g_i := 0, g_{i+1} := 0, \ldots, g_{k-1} := 0;$

- can perform as many decryption operations as he wants;
- knows that his guess $g \in [2^{511}, 2^{512} 1]^{-1}$.

 $^{^{1}}$ The public modulus n in OpenSSL 0.9.7 has a 1024-bit binary representation.

Brumley and Boneh's timing attack - pseudocode

Algorithm 3 Brumley and Boneh's timing attack against OpenSSL

- 1: set g' := g, then $g'_i := 1$;
- 2: compute $u_g = gR^{-1} \mod n$, and $u_{g'} = g'R^{-1} \mod n$;
- 3: measure $t_1 = \text{decryption_time}(u_g)$, and $t_2 = \text{decryption_time}(u_{g'})$;
- 4: compute $\Delta = |t_1 t_2|$;
- 5: **return** 0 if Δ is "large". Otherwise (Δ is "small"), **return** 1.

Note that in step 1., if $q_i = 1$:

- then g < g' < q;
- otherwise, g < q < g'.

Brumley and Boneh's timing attack - why it works

Techniques implemented in OpenSSL (0.9.7) to improve mod_exp:

- Chinese Remainder \rightarrow exposes $q \Rightarrow p = n/q \Rightarrow d = e^{-1} \mod \phi(n)^2$;
- Sliding Windows [5] \rightarrow many multiplications by g;
- ullet Montgomery multiplication [4] o more time required when g < q [6];
- Karatsuba's algorithm \rightarrow less time required when g approaches q from below.

 $^{2}\phi(n) = \phi(p) \cdot \phi(q) = (p-1) \cdot (q-1).$

Lorenzo Palloni

Conclusion

In 1996, Kocher:

- showed that simple mod_exp exposes the exponent;
- prompted improvements on mod_exp implementations.

In 2005, Brumley and Boneh:

- proved that remote timing attacks are practical;
- made crypto libraries to implement blinding by default.

Thanks for your attention!

Do you have any questions?

Appendix

Appendix - Variance estimation in Kocher's attack

The quantity Var(T - T') can be estimated with the formula

$$\frac{1}{s-1}\sum_{j=1}^{s}\left((T_{j}-T'_{j})-\frac{1}{s}\sum_{j=1}^{s}(T_{j}-T'_{j})\right)^{2},$$

recalling that:

- s is the number of generated ciphertexts;
- T_i is the sum of the time required to decrypt the j-th ciphertext;
- $T'_{i} = e + \sum_{i=0}^{b-1} t'_{i}, \quad \forall j \in \{1, \dots, s\};$
- *e* is the overhead time required by the attacker custom decryption;
- b-1 is the index of the guessed bit.

Probability of a correct guess in Kocher's attack (1/5)

An attacker is performing the b-th iteration of the Kocher's attack. We can estimate the probability that d_b^* is correct. Suppose the attacker:

- knows the first b-1 bits of the private exponent x;
- can measure $T' = \sum_{i=0}^{b-1} t'_i$ for each ciphertext y_j , with $j \in \{1, \dots, s\}$;

If x_b is correct, T - T' yields $e + \sum_{i=0}^{k-1} t_i - \sum_{i=0}^{b-1} t_i = e + \sum_{i=b}^{k-1} t_i$.

Probability of a correct guess in Kocher's attack (2/5)

Now, assume that:

- ullet all the time measurements i.i.d. as $\mathcal{N}(0,1)$;
- $Var(T_j T_i') = Var(e + \sum_{i=b}^{k-1} t_i)$ for each ciphertext y_j ;
- the expected variance among all ciphertexts: $Var(e) + (k b)\nu$, with $\nu := Var(t_i) \ \forall i$.

However, if only the first c < b bits of the exponent guess are correct, the expected variance will be $Var(e) + (k + b - 2c)\nu$.

Probability of a correct guess in Kocher's attack (3/5)

Finally, assuming Var(e) negligible, we can state that the following two probabilities are the same:

- that subtracting a correct t'_b from each ciphertext will reduce the total variance more than subtracting an incorrect t'_b ;
- \bigcirc that d_b^* is correct.

In the next two slides, we will show formulas to attain the first probability.

Probability of a correct guess in Kocher's attack (4/5)

$$Pr\left[\frac{1}{s-1}\sum_{j=1}^{s}\left(\sqrt{k-b}X_{j}+\sqrt{2(b-c)}Y_{j}-0\right)^{2}>\frac{1}{s-1}\sum_{j=1}^{s}\left(\sqrt{k-b}X_{j}-0\right)^{2}\right]$$

$$=Pr\left[(k-b)\sum_{j=1}^{s}X_{j}^{2}+2(b-c)\sum_{j=1}^{s}Y_{j}^{2}+\sqrt{2(b-c)(k-b)}\sum_{j=1}^{s}X_{j}Y_{j}>(k-b)\sum_{j=1}^{s}X_{j}^{2}\right]$$

$$=Pr\left[2(b-c)\sum_{j=1}^{s}Y_{j}^{2}+\sqrt{2(b-c)}\sqrt{k-b}\sum_{j=1}^{s}X_{j}Y_{j}>0\right]$$

$$=Pr\left[2\sqrt{2(b-c)(k-b)}\sum_{j=1}^{s}X_{j}Y_{j}+2(b-c)\sum_{j=1}^{s}Y_{j}^{2}>0\right]$$

where $X \sim \mathcal{N}(0,1)$ and $Y \sim \mathcal{N}(0,1)$.

Probability of a correct guess in Kocher's attack (5/5)

Moreover, for s large enough:

- $\sum_{i=1}^{s} Y_i^2 \approx s$
- $\bullet \ \sum_{j=1}^s X_j Y_j \sim \mathcal{N}(0, \sqrt{s}),$

yielding

$$Pr\left(2\sqrt{2(b-c)(k-b)}\left(\sqrt{s}Z\right) + 2(b-c)s > 0\right) = Pr\left(Z > -\frac{\sqrt{s(b-c)}}{2(k-b)}\right)$$
$$= Pr\left(Z < \frac{\sqrt{s(b-c)}}{2(k-b)}\right)$$
$$= \Phi\left(\sqrt{\frac{s(b-c)}{2(k-b)}}\right)$$

where $\Phi(x)$ is the cumulative density function of $\mathcal{N}(0,1)$.
